Randomised controlled trial of smoking cessation intervention after admission for coronary heart disease

Petter Quist-Paulsen, Frode Gallefoss

Abstract

Objective To determine whether a nurse led smoking cessation intervention affects smoking cessation rates in patients admitted for coronary heart disease.

Design Randomised controlled trial.

Setting Cardiac ward of a general hospital, Norway.

Participants 240 smokers aged under 76 years admitted for myocardial infarction, unstable angina, or cardiac bypass surgery. 118 were randomly assigned to the intervention and 122 to usual care (control group).

Intervention The intervention was based on a booklet and focused on fear arousal and prevention of relapses. The intervention was delivered by cardiac nurses without special training. The intervention was initiated in hospital, and the participants were contacted regularly for at least five months.

Main outcome measure Smoking cessation rates at 12 months determined by self report and biochemical verification.

Results 12 months after admission to hospital, 57% (n = 57/100) of patients in the intervention group and 37% (n = 44/118) in the control group had quit smoking (absolute risk reduction 20%, 95% confidence interval 6% to 33%). The number needed to treat to get one additional person who would quit was 5 (95% confidence interval, 3 to 16). Assuming all dropouts relapsed at 12 months, the smoking cessation rates were 50% in the intervention group and 37% in the control group (absolute risk reduction 13%, 0% to 26%).

Conclusion A smoking cessation programme delivered by cardiac nurses without special training, significantly reduced smoking rates in patients 12 months after admission to hospital for coronary heart disease.
Introduction

Smoking cessation after myocardial infarction is associated with a 50% reduction in mortality after three to five years. Reduced mortality is apparent after a few months and increases with time. After a coronary event, 30-45% of patients stop smoking spontaneously. Randomised investigations of smoking cessation after admission to hospital for coronary heart disease have obtained mixed results. Studies of interventions to change lifestyle, where helping patients to quit smoking was only part of the intervention, have not shown any statistically significant effects on smoking cessation rates.

In studies addressing only smoking cessation, those with brief interventions have been ineffective. Three of five trials with longer interventions (4–6 months) have shown increased smoking cessation rates. Only one of these, however, verified that patients had quit smoking by biochemical means.

Fear arousal messages are important in smoking cessation. We aimed to determine whether a nurse led smoking cessation intervention with emphasis on fear arousal affected smoking cessation rates after 12 months among patients admitted for coronary heart disease.

Methods

We invited to participate in our study all patients admitted to Vest-Agder Hospital, Kristiansand, Norway for myocardial infarction, unstable angina, or care after coronary bypass surgery performed at other hospitals. Eligible patients had to be under 76 years of age and daily smokers. We excluded patients with serious illnesses associated with short life expectancies (cancer, chronic obstructive lung disease, renal or liver failure), serious psychiatric problems, alcoholism, and dementia.

The nurses recruited patients two to four days after admission. Participants were randomly allocated to usual care (control group) or intervention. Doctors were not involved in the programme.

Control and intervention groups

Patients were offered group sessions twice a week with the nurses, in which the importance of smoking cessation was mentioned. Sometime during these sessions a video was shown and a booklet handed out, which contained general information on coronary heart disease and advice on quitting smoking. The control group received no further specific instructions on how to stop smoking.

One of three nurses consulted the patients once or twice during their hospital stay. The intervention was based on a 17 page booklet specially produced for the trial. This booklet emphasised the health benefits of quitting smoking after a coronary event. Two illustrations showed the differences in mortality between those who continued smoking after myocardial infarction or unstable angina and those who stopped. One of the illustrations was a bar chart showing a 60% risk reduction for death after five years of quitting, and the other was a linear chart showing that after 13 years 18% of patients who continued smoking died compared with 6% of those who had quit.

On the basis of these figures, the participants were told that they most probably would have another heart attack if they continued smoking (fear arousal message).

The booklet also contained information on how to prevent relapse, how to stop smoking for those who had not stopped or had relapsed, and how to use nicotine replacements. Also explained was how to identify and cope with high risk situations for relapse, with action plans.

The patients were advised not to smoke during their hospital stay. Those with strong withdrawal urges were encouraged to use nicotine replacements (gum or patch). Spouses who smoked were also asked to quit.

The nurses contacted participants by telephone two days, one week, three weeks, three months, and five months after discharge. At six weeks all participants in the intervention group had a consultation at the outpatient clinic with one of the cardiac nurses. The outpatient contacts included prevention of relapses and positive feedback (for example, telling patients who were not still smoking that they already had less chance of another heart attack). The health benefits of quitting were repeated and, if necessary, a fear arousal message given. Those who continued smoking or relapsed were offered additional support and advice.

Outcome measures

The patients were asked to return after 12 months. Smokers who stated that they were still smoking were classified as smokers and those who claimed they had quit and had a nicotine metabolite concentration < 2.0 mmol/mol creatinine in urine were classified as non-smokers.

Results

Patients were recruited from February 1999 to September 2001 (figure). Education and working status differed slightly between the two groups at baseline (table).

Patients in the intervention group had an average of 1.6 (SD 0.7) consultations as inpatients and 1.6 (SD 1.5) as outpatients. They also received a mean of 8.5

Assessed for eligibility (n=1016)

Excluded (n=766)

- Did not smoke (n=395)
- Did not meet inclusion criteria (n=104)
- Refused to participate (n=57)
- Other reasons (n=10)

Randomised (n=250)

Withdrawn because diagnosis later refuted (n=10) (seven allocated to intervention and three allocated to control)

Allocated to intervention group (n=118)

Lost to follow up (n=18): Withdrawn (n=14)
Died (n=3) Changed address (n=1)

Allocated to control group (n=122)

Lost to follow up (n=4): Withdrawn (n=1)
Died (n=2) Changed address (n=1)

Analysed (n=100)

Analysed (n=118)

Flow of participants through trial
A nurse led smoking cessation intervention with at least five months' follow up increased smoking cessation rates among patients admitted to hospital for coronary heart disease. Further intervention had little impact in those patients who smoked while in hospital or at six weeks' follow up. Since there were no differences in smoking cessation rates between the groups at six weeks, we speculate that a long intervention period was an important factor. It is also possible that the initial intervention provided such a strong motivation for abstinence that it prevented later relapses.

Our dropout rate of less than 10% was lower than in comparable studies. Only one patient in the control group, excluding those who died or changed address, was lost to follow up. The dropout rate in the intervention group was higher than in the control group. This may have been a result of the intervention itself.

We believe that our study is the largest to date addressing only smoking cessation, with a long intervention period. The applicability of the results was strengthened by the low dropout rate and by the inclusion of most patients who smoked, regardless of previous coronary heart disease. Further, the principles of the intervention, focusing on fear arousal and relapse prevention, were simple. Assuming a time commitment of 2.4 hours for each patient, a nurse working part time has the capacity to conduct individual smoking cessation programmes on eight patients a week. Assuming that these 15 patients returned to smoking at 12 months, in an intention to treat analysis the smoking cessation rates were 50% (57/114) in the intervention group and 37% (44/119) in the control group (absolute risk reduction 13%, 0% to 26%, number needed to treat 8, 4 to 250).

Predictors of outcome
In a multiple logistic regression analysis of predictors of abstinence, the intervention versus control group (odds ratio 1.93, 1.07 to 3.46) and absence versus occurrence of previous coronary heart disease (2.60, 1.18 to 5.71) showed statistically significant positive associations with cessation (see also bmj.com).

Only 9% (7/80) of the patients who smoked while in hospital or at six weeks' follow up were abstinent at 12 months (three in the intervention group and four in the control group).

Discussion
A nurse led smoking cessation intervention with at least five months' follow up increased smoking cessation rates among patients admitted to hospital for coronary heart disease. Further intervention had little impact in those patients who smoked while in hospital or at six weeks' follow up. Since there were no differences in smoking cessation rates between the groups at six weeks, we speculate that a long intervention period was an important factor. It is also possible that the initial intervention provided such a strong motivation for abstinence that it prevented later relapses.

Our dropout rate of less than 10% was lower than in comparable studies. Only one patient in the control group, excluding those who died or changed address, was lost to follow up. The dropout rate in the intervention group was higher than in the control group. This may have been a result of the intervention itself.

We believe that our study is the largest to date addressing only smoking cessation, with a long intervention period. The applicability of the results was strengthened by the low dropout rate and by the inclusion of most patients who smoked, regardless of previous coronary heart disease. Further, the principles of the intervention, focusing on fear arousal and relapse prevention, were simple. Assuming a time commitment of 2.4 hours for each patient, a nurse working part time has the capacity to conduct individual smoking cessation programmes on eight patients a week. This intervention is probably cost effective compared with other medical treatments in preventing cardiac events and deaths, and we suggest that similar programmes should be provided as part of routine care in wards dealing with cardiac conditions.

We thank the cardiac nurses Tone Baeck, Eva Borroey, and Anne Kari Kjellesvik for delivering the intervention and collecting data.

Hospital bed utilisation in the NHS, Kaiser Permanente, and the US Medicare programme: analysis of routine data

Chris Ham, Nick York, Steve Sutch, Rob Shaw

Abstract

Objective To compare the utilisation of hospital beds in the NHS in England, Kaiser Permanente in California, and the Medicare programme in the United States and California.

Design Analysis of routinely available data from 2000 and 2001 on inpatient admissions, lengths of stay, and bed days in populations aged over 65 for 11 leading causes of use of acute beds.

Setting Comparison of NHS data with data from Kaiser Permanente in California and the Medicare programme in California and the United States; interviews with Kaiser Permanente staff and visits to Kaiser facilities.

Results Bed day use in the NHS for the 11 leading causes is three and a half times that of Kaiser’s standardised rate, almost twice that of the Medicare California’s standardised rate, and more than 50% higher than the standardised rate in Medicare in the United States. Kaiser achieves these results through a combination of low admission rates and relatively short stays. The lower use of bed days in Medicare in California compared with Medicare in the United States suggests there is a “California effect” as well as a “Kaiser effect” in hospital utilisation.

Conclusion The NHS can learn from Kaiser’s integrated approach, the focus on chronic diseases and their effective management, the emphasis placed on self care, the role of intermediate care, and the leadership provided by doctors in developing and supporting this model of care.

Introduction

Feachem and colleagues have compared the costs and performance of the NHS and the health maintenance organisation Kaiser Permanente in California. They reported at the aggregate level that the NHS used three times the number of acute bed days as Kaiser.

To explore the issues raised in their analysis further, we took a number of the leading causes of bed day use in the NHS and compared resource utilisation for each cause. In so doing, we sought to understand how Kaiser is able to limit the use of beds for conditions such as stroke and hip fracture, which are a major source of demand on NHS hospitals.

We concentrated on people aged 65 and over because older people make the greatest use of acute beds. Also, focus on this age group enables the comparison between the NHS and Kaiser to be located in the context of the utilisation of services by the Medicare population for the United States as a whole and in California.

Throughout the paper we use the term Kaiser as shorthand for the Kaiser Permanente Medical Care Programme. The programme is made up of the Kaiser Foundation Health Plan, Kaiser Foundation Hospitals, and the Permanente Medical Groups. There are more than 10 000 Permanente physicians in the medical groups and they serve more than 8 million Kaiser Permanente members.

Methods

We used routinely available data from the hospital episodes statistics for 2000-1 to identify 11 leading
